Abstract

The current congestion-oriented design of TCP hinders its ability to perform well in hybrid wireless/wired networks. We propose a new improvement on TCP NewReno (NewReno-FF) using a new loss labeling technique to discriminate wireless from congestion losses. The proposed technique is based on the estimation of average and variance of the round trip time using a filter, called Flip Flop filter, that is augmented with history information. We show the comparative performance of TCP NewReno, NewReno-FF, and TCP Westwood through extensive simulations. We study the fundamental gains and limits using TCP NewReno with varying Loss Labeling accuracy (NewReno-LL) as a benchmark. Lastly our investigation opens up important research directions. First, there is a need for a finer grained classification of losses (even within congestion and wireless losses) for TCP in heterogeneous networks. Second, it is essential to develop an appropriate control strategy for recovery after the correct classification of a packet loss.

1. Introduction

The Transmission Control Protocol (TCP) has been the dominant transport mechanism for reliable data transfer over the Internet. While the Internet is growing in size and becoming increasingly heterogeneous, network designers are faced with the challenging question of how to empower TCP so it works well in such hybrid wired/wireless environment [19], where packets can be lost because of various reasons. Many studies have shown that TCP throughput can be improved if the cause of a packet loss is identified. TCP was originally designed for a wired environment where packets are lost mainly due to congestion (i.e. buffer overflow), and the congestion control algorithms imbedded therein act accordingly. When a TCP connection extends over wireless links, packet losses over such links occur primarily due to channel errors or during handoff. By attributing a packet loss to wireless transmission errors, the TCP source can refrain from taking unnecessary "congestion" control measures. One set of solutions (e.g. Snoop [1], WTCP [16]) require support from the base station located at the interface between the wired infrastructure and the wireless access infrastructure. These solutions incur the cost of implementation at the base station and some violate the end-to-end semantics of TCP.

In this paper, we are primarily interested in *end-to-end* solutions, i.e. those which do not require any support from the network. Proposed end-to-end solutions differ in the measure(s) they use to infer the cause of a packet loss. These measures may be estimated at the sender without any support from the receiver (e.g. round-trip delay), or may require support from the receiver (e.g. one-way delay or delay variance) [15, 4].

Loss classification can be *implicit* in the congestion control of a protocol. TCP Westwood [12] is such a sender-side modification of TCP Reno which estimates the rate that a connection is getting based on the rate at which the sender receives the ACKs. TCP Westwood uses the estimated bandwidth in setting the congestion window and slow start threshold ($ssthresh$) parameters. This is in contrast to regular TCP implementations where the window size is arbitrarily cut in half whenever a loss is detected [6]. This explicit bandwidth estimation scheme is shown to have a positive impact on the performance of TCP Westwood sources, especially in the presence of random, sporadic losses typical of wireless links or over paths with high bandwidth-delay product.

Many proposals tried to classify the losses *explicitly* through different estimation techniques. For example, Samaraweera [17] presents a method, called Non-

*This work was supported in part by NSF grants ANI-0095988 and EIA-0202067, and grants from Sprint and Motorola Labs.

Congestion Packet Loss Detection (NCPLD), to categorize the nature of the error. It uses the concept of the *knee point* of the throughput-load graph at which the network operates at optimum power. If the current (measured) round trip delay is less than the delay threshold at the knee point then the packet loss is assumed to be a wireless loss else it is assumed that congestion (buffer overflow) caused the error.

In [4], Kim *et al.* present an algorithm called Linear Increase/Multiplicative Decrease with History (LIMD/H). It uses explicit support from the receiver to send the loss rate back to the TCP source. Based on this loss rate, the sender estimates the goodput. If the current goodput is below a certain band around the mean, then the cause of a packet loss is assumed to be congestion, otherwise the cause of loss is attributed to wireless errors. LIMD/H backs off its transmission window less conservatively to wireless losses than to congestion-induced losses.

Our Contribution: In this paper, we study the fundamental gains and limits of *explicit* loss labeling techniques. Explicit loss labeling may be advantageous as it provides a clean separation between the process of inferring the *cause* of a packet loss and the control (recovery) process that may make use of it. To this end, we consider a generic loss labeling technique for which we can vary its accuracy in correctly attributing a packet loss to either congestion or wireless error. We refer to this generic technique as *NewReno-LL* since we empower the TCP NewReno version with loss labeling. We have only chosen NewReno as recent measurements show that the majority of TCP implementations are NewReno [14]. *NewReno-LL* is thus used to cover the spectrum of explicit loss labeling techniques described above. Note that each explicit loss labeling technique arrives in a different way at a particular loss labeling accuracy.

We also propose a new explicit loss labeling technique that would result in a certain loss labeling accuracy under a particular configuration. The motivation behind our proposal is that we assume the variation in round trip times (RTT) and the nature of loss are correlated [11]. Therefore, a good estimation of RTT or observed delay can help TCP identify wireless losses and in turn TCP could react less conservatively to them. In our estimation technique, we make use of a Flip Flop filter [9] in estimating the average RTT. We use the 3-sigma rule [10] to account for the variance. Note that there are many techniques to estimate the mean and variance but we are interested in one that is simple and sufficiently accurate. The effectiveness of the Flip Flop filter in filtering out transients and capturing persistent conditions was shown in [9]. In this paper, we re-instantiate the filter to measure RTT and augment it with *history* information so as to distinguish between congestion and wireless losses, specifically to empower TCP NewReno in wired/wireless networks. We henceforth refer to our loss labeling technique as *NewReno-FF*.

The rest of the paper is organized as follows. In Section 2, we propose a loss prediction algorithm (NewReno-FF) to predict the cause of a packet loss. We also describe other schemes against which we compare NewReno-FF. In Section 3, we discuss the performance metrics used to evaluate the various loss predictors. Section 4 presents an analytical model of our generalized loss labeling technique, NewReno-LL. Section 5 argues for convergence to fairness and efficiency when a NewReno flow and a NewReno equipped with loss labeling compete in the presence of both congestion-induced and random wireless drops. Section 6 evaluates the performance of loss predictors using the *ns*-2 network simulator [18]. Section 7 discusses directions for future research and concludes the paper.

2. Evaluated Schemes

2.1. TCP NewReno-LL

TCP NewReno inherently has no loss prediction ability; it considers all losses to be congestion losses. We denote by $P[C|C]$ ($P[W|W]$), the probability that a loss predictor classifies a packet loss as congestion (wireless) loss given that it is indeed caused by congestion (wireless) error [2].Thus for TCP NewReno, $P[C|C] = 1$ and $P[W|W] = 0$. Ideally we want to have a protocol with $P[C|C] \approx 1$ but also high $P[W|W]$ so as to react appropriately based on the type of loss. $P[C|C] \approx 1$ is highly desirable so as not to congest the network. High $P[W|W]$ enables the protocol to avoid taking unnecessary congestion control steps.

To evaluate the limits of TCP NewReno we evaluate it against TCP NewReno equipped with varying loss classification accuracies (NewReno-LL). In NewReno-LL, on a loss event, the sender reduces its congestion window with probability $P[C|C]$ if the loss is a congestion one and *ignores* the window adjustment with probability $P[W|W]$ if it is a wireless loss. In the perfect loss labeling version, NewReno-PL, we have $P[C|C] = 1$ and $P[W|W] = 1$. We note that, although we assume fixed values for $P[C|C]$ and $P[W|W]$, in general these values depend on the parameters of the network as well as the loss classification algorithm. Furthermore, ignoring window adjustments in the case of wireless losses is not necessarily optimal. We only consider this control action for simplicity and so as to gain insight into the

fundamental issues. We can imagine window adjustments that match particular levels of error.

2.2. TCP NewReno-FF

We propose a new loss labeling scheme for distinguishing wireless losses from congestion losses. In this scheme, using an adaptive Flip Flop filter [9], a parallel estimation of RTT is done on every new ACK received in NewReno. TCP usually uses one exponentially weighted moving average (EWMA) filter which is static. The Flip Flop filter uses two EWMA filters, one is stable and another is agile. An agile filter is one which gives more weight to recently observed samples unlike a stable filter. The underlying principle is to employ an agile filter whenever possible but switch to the stable one when the RTT samples vary drastically and become noisy. According to statistical quality control, control limits are defined around the current sample mean and when the samples exceed the control limits, the process is said to be out of control. To estimate the deviation, the filter uses a moving range which it estimates from the samples within the control limits. The control limits are defined as:

$$\overline{x} \pm 3\frac{\overline{MR}}{d_2} \quad (1)$$

where $\overline{x}$ is the sample mean, $\overline{MR}$ is the Moving Range which is the average of the differences between adjacent RTT samples, $|x_i - x_{i-1}|$, and d_2 estimates the standard deviation of a given sample given its range. When the range is from a sample of two, as for MR, $d_2 \approx 1.128$ [10].

The basic tenet of our approach is that if the packets are suffering congestion losses, the observed RTTs will vary but if packets are suffering random losses, the observed RTTs will not vary much. Using the Flip Flop filter, we define an upper control limit on RTT using (1). We then consider the much delayed packets, whose RTT exceeds the control limit, as "outliers." More than η outliers in the last l samples are used as congestion indication. η and l are tunable parameters. The pseudo code of the loss labeling is given in Figure 1.

Modified Recovery Strategy: When NewReno-FF detects a packet loss based on duplicate ACKs[1], it checks if the sender has received more than η outlier samples in the last l samples. If the number of outliers is more than η, it continues with usual congestion control steps otherwise it ignores it assuming a wireless loss. The pseudo code of the modified recovery part of TCP NewReno is given in Figure 2.

[1]TCP detects loss either due to timeout or three consecutive duplicate acknowledgments.

```
if (s_rtt > est_rtt+3MR/1.128) then
   vector = vector ≪ 1 // Left shift once
   vector = vector OR 0x01 // Bitwise OR
   est_rtt = 9/10 est_rtt + 1/10 s_rtt //stable RTT filter
else
   vector = vector ≪ 1 // Left shift once
   vector = vector OR 0x00 // Bitwise OR
   est_rtt = 1/10 est_rtt + 9/10 s_rtt // agile RTT filter
   if (s_rtt ≥ est_rtt-3MR/1.128) then
      diff = |s_rtt − last_rtt|
      MR = 0.875MR + 0.125diff
   end if
end if
if (first ack) then
   vector = 0x00; // initialize bit vector of l bits
   est_rtt = s_rtt
   MR = est_rtt/2
end if
```

```
if (error detected based on dup acks) then
   if (#bits set in vector ≤ η) then
      no change in congestion window and ssthresh
      // classified as wireless loss
   else
      do normal congestion window and ssthresh adjustment // classified as congestion loss
   end if
end if
```

Figure 2. Modified recovery strategy

We are still assuming that *all* timeouts indicate congestion, i.e. we do not attempt to classify timeout-detected losses as congestion versus wireless. It is known that timeouts caused by wireless losses can degrade the performance of regular TCP implementations, which may back off very conservatively [19]. We account for these effects through our TCP NewReno variant with perfect loss labeling.

2.3. TCP Westwood

We have also compared the performance of TCP Westwood which doesn't have any explicit loss labeling mechanism. However, it is claimed that the bandwidth estimation of TCP Westwood accounts for the wireless losses [12].

3. Performance Metrics

We have compared the schemes described in Section 2 based on the following metrics:

- Goodput: The rate of delivery of useful data. We measure the goodput at the receiver.
- Overhead: 1-$\frac{\text{Goodput}}{\text{Throughput}}$. We measure throughput as the rate at which the receiver is receiving data. Note that this measure reflects the overhead of re-transmissions.
- $P[W|W]$: This metric indicates the accuracy in wireless loss classification. It defines the probability of identifying a loss as a wireless loss given that the loss is indeed a wireless loss.
- $P[C|C]$: This metric indicates the accuracy of congestion loss classification. It defines the probability of identifying a loss as a congestion loss given that the loss is indeed a congestion loss.
- Fairness: Reflects the fair share distribution across N various connections. It is given by:

  $$\text{Fairness Index} = \frac{(\sum_{i=1}^{N} T_i)^2}{N \sum_{i=0}^{N} T_i^2}$$

  where T_i is the throughput of the i^{th} connection [7].
- TCP-compatibility: This metric measures how fair a loss prediction-capable protocol is when it competes with regular TCP NewReno. It is defined as $\frac{G_h}{G_o}$, where G_h is the average goodput attained by n NewReno flows competing with n other flows of the protocol, and G_o is the average goodput of n NewReno flows competing with n other NewReno flows under the same conditions. Thus a value close to 1 indicates compatibility in a heterogeneous setting. On the other hand, a value less than 1 indicates that the loss prediction-capable protocol is grabbing more bandwidth.

4. Stochastic Model of NewReno-LL

In this section, we derive a simple fluid model for NewReno-LL to illustrate the effect of $P[C|C]$ and $P[W|W]$ on throughput. We follow the same lines of analysis as in [5]. For simplicity, we do not consider timeouts. We assume that the transmission window is reduced by half *only* if the packet loss is identified as congestion-induced.

For a window size of W (packets), the window increases by $\frac{1}{W}$ on every ACK reception. This is the *additive increase* of TCP. We assume packet loss happens with a probability $p = 1-(1-p_c)(1-p_w)$, where p_c and p_w are the congestion and wireless drop rates, respectively. The window decreases by $\frac{W}{2}$ with probability $p_c P[C|C] + (1-p_c)p_w P[C|W]$, i.e. whenever the packet loss is classified (or misclassified) as congestion-induced. To make the notation more readable, we denote $P[C|C]$ by $p_{c/c}$ and $P[C|W]$ by $p_{c/w}$.

The expected change in the window is given by:

$$\begin{aligned} E[\Delta W] &= \frac{(1-p_c)(1-p_w)}{W} \\ &\quad -\frac{W}{2}(p_c p_{c/c} + (1-p_c)p_w p_{c/w}) \end{aligned} \quad (2)$$

Since W is updated at approximately every $\frac{RTT}{W}$, using Equation (2), the expected change in the sending rate (throughput) r per unit time is approximately:[2]

$$\begin{aligned} \frac{dr(t)}{dt} &= \frac{(1-p_c)(1-p_w)}{RTT^2} - \\ &\quad \frac{r^2(t)(p_c p_{c/c} + (1-p_c)p_w p_{c/w})}{2} \end{aligned} \quad (3)$$

By rearranging and integrating we have:[3]

$$r(t) = \frac{\left\{\frac{1+Ce^{-2at}}{1-Ce^{-2at}}\right\}}{RTT}\sqrt{\frac{2(1-p_c)(1-p_w)}{p_c p_{c/c} + (1-p_c)p_w(1-p_{w/w})}} \quad (4)$$

where a is given by $\sqrt{\frac{(1-p_c)(1-p_w)(p_c p_{c/c}+(1-p_c)p_w(1-p_{w/w}))}{2\,RTT^2}}$ and C depends on initial conditions.

The steady state throughput of NewReno-LL is thus given by:

$$\begin{aligned} r &= \lim_{t\to\infty} r(t) \\ &= \frac{1}{RTT}\sqrt{\frac{2(1-p_c)(1-p_w)}{p_c p_{c/c} + (1-p_c)p_w(1-p_{w/w})}} \end{aligned} \quad (5)$$

From Equation (5), we can observe the significance of $p_{c/c}$ and $p_{w/w}$ on the throughput of a connection. A higher value of accurate congestion loss classification, $p_{c/c}$, reduces throughput. On the other hand, a higher value of accurate wireless loss classification, $p_{w/w}$, increases throughput. Note, however, that we are assuming fixed drop rates and classification probabilities. In reality, these loss and classification probabilities would depend on the number of competing

[2]Note that $r(t) = W(t)/RTT$.

[3]Note that $p_{c/w} + p_{w/w} = 1$.

connections, network conditions and the behavior of the protocol. In particular, p_c, assumed fixed in traditional analytical studies [13], depends on $p_{c/c}$, $p_{w/w}$ and r. The throughput r in turn depends on p_c, $p_{c/c}$ and $p_{w/w}$. In general, it is very difficult to solve analytically for closed-form expressions for throughput and other performance measures. In Section 6, we resort to simulations to evaluate the effectiveness of loss labeling techniques.

5. TCP-compatibility and Convergence

In this section, we argue that two competing flows, one regular TCP (NewReno) and another TCP equipped with loss prediction (e.g. NewReno-FF), would still converge to fairness and efficiency in the presence of both congestion-induced and random wireless drops, given that the loss classification is accurate.

Assuming ideal synchronized feedback, we use the technique of Chiu and Jain to represent the two-source case as a "phase plot" [3]. The axes correspond to the window sizes of each source. As the system evolves over time, each source adjusts its transmission window based on the network state and the control algorithm leading to a trajectory in the phase space. According to the linear controls of Additive Increase Multiplicative Decrease (AIMD), the trajectory moves parallel to 45^o-line during additive increase. During multiplicative decrease, the trajectory moves along the line joining the current state to the origin. Fairness, defined as the ratio of the windows, improves during additive increase, and remains unchanged during the decrease phase.

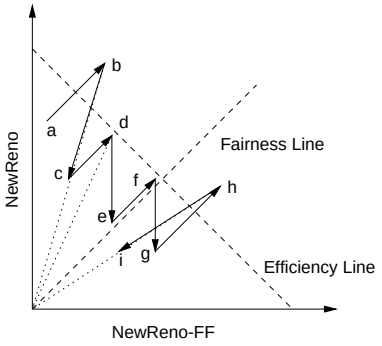

Figure 3. Convergence of NewReno vs. NewReno-FF

Referring to Figure 3, without loss of generality, suppose NewReno and NewReno-FF start at point a. Both sources linearly increase their windows and both experience congestion drops at point b when the windows overshoot the efficiency (maximum capacity) line. Both the sources then reduce their windows evolving to the under-utilized region but closer to fairness at point c. Subsequently, assume the sources experience wireless drops at points d and f, NewReno-FF avoids unnecessary backoff while NewReno backs off. It is easy to see that, in cases of random wireless drops, NewReno-FF grabs more resources evolving the system away from the fairness line. However, congestion losses and accurate classification drive the system back toward the fairness line (transition from h to i).

The argument can be extended to multiple sources by considering the sources pairwise. Our simulation results in Section 6 substantiate this convergence behavior.

6. Simulation Model and Methodology

We use the network simulator *ns*-2 (version 2.1b8a) [18]. The network topology used in the simulation is shown in Figure 4.

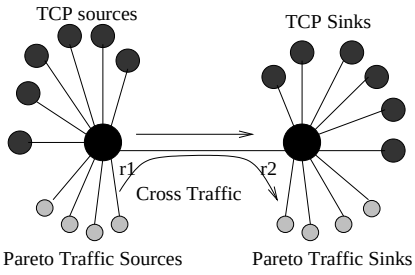

Figure 4. Wireless Last Hop Topology

We have a number of TCP traffic source-destination pairs. The link from $r2$ to each TCP traffic sink has been assigned 2Mbps bandwidth and 0.01ms propagation delay. These links represent wireless links with transmission errors. The loss rate on each wireless link is set at 5% to represent low to medium range wireless errors. All other links are error free with 10Mbps bandwidth and 1ms propagation delay except the shared (bottleneck) wired link $r1 \rightarrow r2$ whose bandwidth is 10Mbps and propagation delay is 50ms. The buffer size at $r1 \rightarrow r2$ is set to an integer multiple of the bandwidth-delay product ($127 \times n$ packets for $n \geq 1$). All other buffer sizes are set to a default value of 50 packets. All the TCP sources and the cross traffic on-off sources are started randomly at time $t \in [0, 3]$ sec and the simulations are stopped at time 200 sec. For each UDP-based cross traffic source, the duration of the on and off periods are Pareto distributed and varied for each configuration. We calculate the performance measures within 95% confidence intervals.

6.1. Simulation Results

Configuration 1: The on and off periods of each of the 10 background cross traffic sources follow a Pareto distribution with shape parameter 1.5 and average duration of 45ms and 10ms, respectively. The sending rate of each cross traffic source is 0.2 Mbps while it is on, so as to have negligible congestion loss at $r1 \rightarrow r2$ when all 20 competing long-lived TCP flows are NewReno. The buffer size at $r1 \rightarrow r2$ is set to four times the bandwidth-delay product. For our loss labeling technique, the values for l and η are 10 and 5, respectively.[4]

Figure 5(a) shows the goodput of NewReno-LL against varying $P[W|W]$. Figure 5(b) shows TCP-compatibility (normalized goodput) when 10 NewReno flows compete with 10 NewReno-LL flows. Table 1 summarizes the performance of different schemes in terms of other metrics (defined in Section 3) when all 20 TCP flows are homogeneous. Recall that NewReno-PL, the perfect loss labeling version, is a special case of NewReno-LL with $P[C|C] = P[W|W] = 1$.

Configuration 2: The on and off periods of each of the 30 background cross traffic sources follow a Pareto distribution with shape parameter 2.5 and average duration of 100ms each. The sending rate of each cross traffic source is 0.6 Mbps while it is on, so as to have around 1% congestion loss at $r1 \rightarrow r2$ when all 10 competing long-lived TCP flows are NewReno. The buffer size at $r1 \rightarrow r2$ is set to the bandwidth-delay product. For our loss labeling technique, the values for l and η are 8 and 4, respectively.

Figure 6(a) shows the goodput of NewReno-LL against varying $P[W|W]$. Figure 6(b) shows TCP-compatibility (normalized goodput) when 5 NewReno flows compete with 5 NewReno-LL flows. Table 2 summarizes the performance of different schemes in terms of other metrics (defined in Section 3) when all 10 TCP flows are homogeneous.

6.2. Observations and Discussion

- For both configurations, NewReno-FF achieves a goodput higher than that of NewReno, Westwood, and NewReno-LL for all values of $P[C|C]$ and $P[W|W]$. Recall that NewReno corresponds to $P[C|C] = 1$ and $P[W|W] = 0$. NewReno-FF achieves higher goodput without losing much in terms of fairness index. However, NewReno-FF has higher overhead than NewReno, which has the least overhead.

- Although NewReno-FF adapts its $P[C|C]$ and $P[W|W]$ values according to the network conditions, the average values of $P[C|C]$ and $P[W|W]$ in both configurations are observed to be lower than one would expect. In configuration 1, the average values of $P[C|C]$ and $P[W|W]$ for NewReno-FF are found to be 0.0 and 0.84, respectively, when all TCP sources are NewReno-FF. When NewReno-FF flows compete with NewReno flows, the values are 0.0 and 0.61. Note that in configuration 1, we intended to have negligible congestion. Therefore, $P[C|C]$ indeed shows accurate labeling by *not* classifying rare (non-persistent) congestion events as congestion.

  Similarly, for configuration 2, we observe the the average values of $P[C|C]$ and $P[W|W]$ for NewReno-FF to be 0.32 and 0.65, respectively, when all TCP sources are NewReno-FF. When NewReno-FF flows compete with NewReno flows, the values are 0.42 and 0.63, respectively. This means that $P[W|C] \approx 0.68$ and 0.58, respectively. This high value of congestion misclassification probability makes NewReno-FF more aggressive and consequently has the highest goodput. Note that the loss misclassification in NewReno-FF can sometimes be viewed as *finer* classification—for example, misclassifying *short-term* congestion as wireless and thus avoiding unnecessary window backoff may be beneficial.

- To justify the lower values of $P[C|C]$ and $P[W|W]$ for NewReno-FF, we need to reconsider the definitions of the two metrics. The values of $P[C|C]$ and $P[W|W]$ much depend on the agility and stability of the filter. In our experiments, the Flip Flop filter is stable enough to filter out low frequency transient changes. The random wireless losses and even short-term congestion losses fall into this category. Therefore, the Flip Flop filter classifies many short-term congestion losses as wireless losses, thus the transmission window is not reduced. Although this "misclassification" lowers $P[C|C]$, this may in fact be a more appropriate control strategy. The loss classification process for a TCP flow is illustrated in Figure 8 for configuration 2. We don't have timeout cases over the shown time interval.[5] We have plotted the in-

[4] Recall that l and η are tunable parameters in our FF-based loss classification technique. A short history is found to generally improve goodput and TCP-compatibility; see Figure 7. In general, l and η depend on the network configuration and may be adjusted dynamically. We leave this as future work.

[5] Recall that in this paper, timeouts do not contribute to our loss classification process, only duplicate ACKs.

Figure 5. Goodput and TCP-compatibility of NewReno-LL as a function of $P[W|W]$ (configuration 1)

Protocol	Goodput(Kbps)	Throughput	Fairness	TCP-compatibility
NewReno	229.9	230.7	0.9958	1.00
NewReno-FF(10,5)	375.6	397.0	0.9935	0.97
Westwood	352.8	354.9	0.9974	0.96
NewReno-LL Best($P[C\|C], P[W\|W]$)	358.1 (1, 0.6)	397.7 (1, 1)	0.9961 (1, 0.4)	0.99 (1,0.2)
NewReno-LL Worst($P[C\|C], P[W\|W]$)	0.02 (0, 1)	0.1 (0, 1)	0.005 (0, 1)	0.50 (0, 1)

Table 1. Comparison of performance metrics for different schemes (configuration 1)

stantaneous queue length of the shared wired link, the instances of queue drops, wireless drops, and duplicate ACKs.

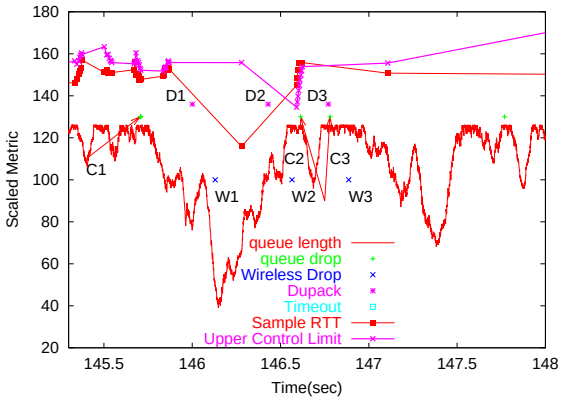

Figure 8. TCP dynamics (configuration 2). Actual RTT values (in secs) are 1/900 times what is shown on the y-axis

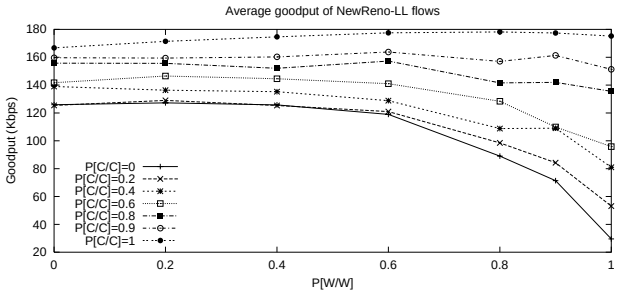
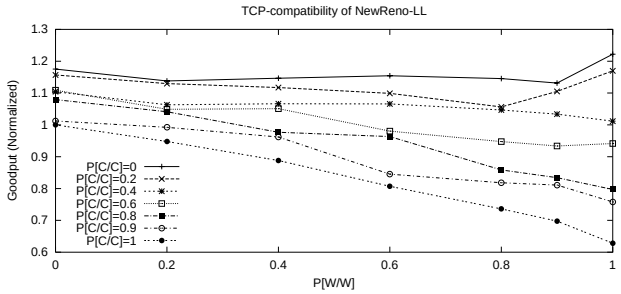
When the queue drop $C1$ happens at 145.706 sec, the last l samples are below the threshold η of our loss labeling technique, therefore window adjustment is not done on the duplicate ACK, $D1$ at 146.001 sec. Observe that this action seems appropriate as the queue length drops indicating that congestion has subsided. In effect, the filter classifies this to be a case of "transient" congestion loss whereas NewReno would have simply reduced the $ssthresh$ and congestion window. The error detection event based on duplicate ACKs, $D2$ at 146.43 is caused by a wireless drop, $W1$ but since the history of not enough outliers is there, this wireless loss will be correctly classified as a wireless loss and the congestion window is not reduced in this case.

As congestion builds up, many samples may be detected as outliers and if the congestion is persistent, the number of samples arriving at the sender will reduce. Therefore, outliers appearing in the growing phase of the bottleneck queue will retain the bad history for long if the values of l and η are chosen properly. On the other hand, if the congestion is transient, more samples will arrive subsequently and the bad history can soon be shaken off. The queue drop, $C2$ in Figure 8, is preceded by more than η outlier samples, therefore, the filter classifies the loss as congestion at $D3$, thus the transmission window is reduced. From the buffer occupancy, we can see that it is appropriate to be conservative on $D3$.



(a) Goodput of NewReno-LL versus $P[W|W]$



(a) Normalized Goodput versus $P[W|W]$

Figure 6. Goodput and TCP-compatibility of NewReno-LL as a function of $P[W|W]$ (configuration 2)

Protocol	Goodput(Kbps)	Throughput (Kbps)	Fairness	TCP-compatibility
NewReno	166.7	167.5	0.9910	1.00
NewReno-FF(8,4)	187.3	202.5	0.9616	0.75
Westwood	177.9	183.7	0.9888	0.85
NewReno-LL	178.2	216.8	0.9912	1.23
Best($P[C\|C], P[W\|W]$)	(1, 0.8)	(1,1)	(1, 0.2)	(0,1)
NewReno-LL	29.56	43.2	0.318	0.63
Worst($P[C\|C], P[W\|W]$)	(0,1)	(0,1)	(0.4, 1)	(1,1)

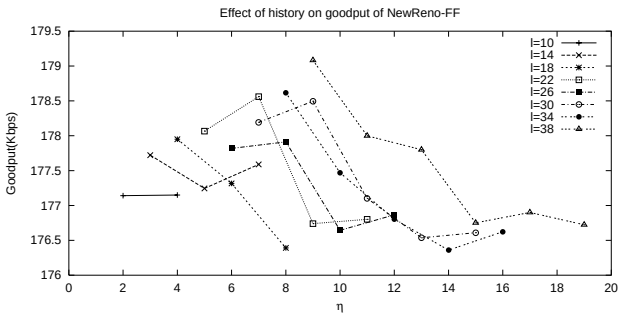
Table 2. Comparison of performance metrics for different schemes (configuration 2)

- NewReno with Perfect Labeling (NewReno-PL) is not necessarily optimal in terms of goodput. Although it seems reasonable to take a control action (such as ignoring window adjustment in wireless loss cases) based on the *exact* nature of a *past* loss (as in NewReno-PL), such control action may not always be correct or may not yield better performance globally. This is because of the delayed feedback. By the time the feedback reaches the senders, the *actual* network state might have changed.

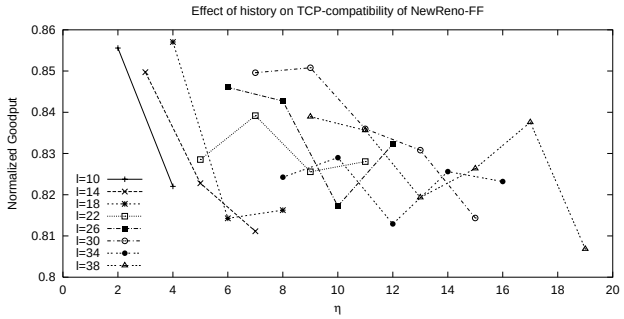
  In NewReno-LL, on a loss event, the senders reduce their transmission window with probability $P[C|C]$ if the loss is a congestion one, and ignore window adjustments with probability $P[W|W]$ if it is wireless loss. Such randomization of the control actions may improve goodput by making the system more robust—for example, if the congestion loss was transient, then having some sources misclassifying it as wireless and thus not backing off their transmission rate may be beneficial.

- NewReno-LL can achieve highest goodput at $P[C|C] = 1$ and high $P[W|W]$. However, NewReno-LL performs poorly for low $P[C|C]$ and $P[W|W] = 1$. Unlike NewReno-FF, $P[C|C]$ and $P[W|W]$ for NewReno-LL are artificially static and do not depend on network conditions. This causes NewReno-LL to be overly aggressive, thus overloading the network and degrading its own performance. This is apparent from the degradation in goodput as $P[W|W]$ exceeds a value of around 0.8 in configuration 1 and 0.6 in configuration 2. We also observe from the TCP-compatability measure that beyond these $P[W|W]$ values, a low $P[C|C]$ causes NewReno-LL to experience excessive losses, losing its self-clocking of new packets, hence giving up more bandwidth to competing regular NewReno flows.

- Table 2 also shows increased aggressiveness in the behavior of NewReno-FF evidenced by low TCP-compatility when it competes with regular NewReno. Unlike regular NewReno, a NewReno-FF flow does not back off its transmission window if it classifies a loss as wireless. Otherwise, NewReno-FF cuts its window in half according to regular AIMD rules. For any AIMD scheme to be TCP-compatible, the window increase and decrease parameters, α and β, must satisfy the necessary condition of TCP-friendliness given by $\alpha = \frac{3\beta}{2-\beta}$ (without considering the timeout effects) [8].



(a) Goodput as a function of l and η



(a) TCP-compatibility as a function of l and η

Figure 7. Effect of history on goodput and compatibility of NewReno-FF (configuration 2)

If loss labeling is not perfectly accurate, the effective value of β, β_e, is given by:

$\beta_e = \frac{1}{2}(P[C|C]+P[C|W])+0(P[W|W]+P[W|C])$.

For a perfect labeling case, we have $P[C|C] = 1$ and $P[C|W] = 0$, which implies $\beta = 1/2$ and $\alpha = 1$ as in regular TCP. However, in our configurations, NewReno-FF shows a lower β_e and hence a lower α should be used when the window is linearly increased.

Figures 9(a) and (b) show the window dynamics of a NewReno flow competing with a NewReno-FF flow. The aggressiveness of NewReno-FF is reduced, hence TCP-compatibility can be improved, for a lower increase parameter, α.

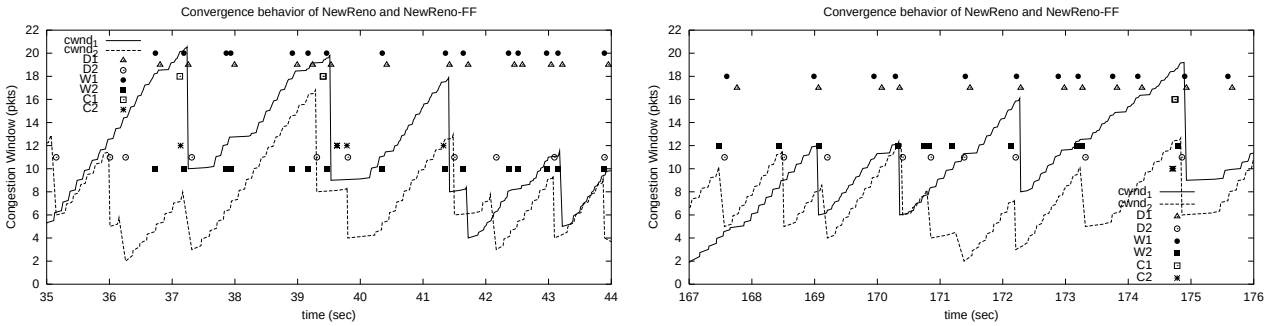
7. Conclusions and Future Work

In this paper, we attempted to improve our understanding of the fundamental gains and limitations of loss classification techniques employed to empower TCP in hybrid wired/wireless networks. To this end, we abstract the general approach of various proposals by controlling the loss labeling accuracies, $P[C|C]$ and $P[W|W]$. These two measures quantify the probability that an event is identified correctly. In all proposals, this event is only one of two possibilites: congestion-induced loss or wireless loss. Such loss classification can be used to empower the recovery strategy of TCP. For example, the usual congestion control measure of backing off the transmission rate is taken if the packet loss is attributed to congestion. However, if the packet loss is attributed to wireless, a different control action is taken— in this paper, we assume an aggressive strategy whereby the transmission rate is kept unchanged.

We also introduced a new loss labeling technique that uses a Flip Flop filter to estimate RTT and use it to differentiate between congestion and wireless loss. Our technique uses *history* to examine the number of "outlier" RTT samples, i.e. those samples that exceed a control limit beyond which delay values are considered high. A packet loss is classified as congestion-induced if enough outliers are observed.

Through extensive simulations, we show that our loss labeling-based technique outperforms regular TCP and TCP Westwood in terms of goodput while maintaining competitive fairness. We also observe the low values of $P[C|C]$ and $P[W|W]$ under our Flip Flop based technique. This does *not* mean that our FF-based classification is inaccurate. Rather, the low value of $P[C|C]$ implies a higher value of $P[W|C]$.This is the case when short-term congestion losses are treated as random wireless losses or more generally, *transient* losses. This is indeed an appropriate (in effect, finer grained) loss classification. Based on these observations, we believe that there is a need for such fine grained classification that goes beyond a binary classification of congestion versus wireless. Furthermore, this opens up the important research question of what kind of recovery actions should a protocol like TCP implement given the correct classification of packet losses.

We are currently analyzing our FF-based loss classification technique mathematically. We are also generalizing this analysis to any technique as a function of $P[C|C]$ and $P[W|W]$, or finer classification accuracies. We again note that the values of $P[C|C]$ and $P[W|W]$ depend on the parameters of the network as well as the loss classification algorithm. The ultimate goal is to develop a fine grained loss classification technique with an associated *adaptive* recovery strategy which enhances goodput and fairness while maintaining low overhead and high compatibility over hybrid wireless/wired networks. An ideal recovery strategy would match the level and density of error to appropriate transmission window adjustments. Lowering overhead is especially important for battery-operated devices.



(a) NewReno-FF ($\alpha = 1.0$) competing with NewReno (b) NewReno-FF ($\alpha = 0.8$) competing with NewReno

Figure 9. Convergence of NewReno-FF (solid line) and NewReno (dashed) for configuration 2. Rate of each cross traffic source changed to 0.6Mbps and loss rate on each wireless link 2%. $cwnd_1, D1, W1, C1$ **(**$cwnd_2, D2, W2, C2$**) indicate the window and instances of dup acks, wireless and congestion drops of NewReno-FF (NewReno)**
